

Python Programming

Module 9: Classes

Learning objectives

1. How to write your own classes.
2. How to store information in a class using attributes and how to write methods that give your classes the behavior they need.
3. How to modify the attributes of an instance directly and through methods.
4. How inheritance can simplify the creation of classes that are related to each other.
5. Using instances of one class as attributes in another class to keep each class simple.

Classes

Python has been an object-oriented language since it existed. Because of this, creating and using classes and objects are downright easy. here is small introduction of Object-Oriented Programming (OOP) to bring you at speed.

Overview of OOP Terminology

Class – A user-defined prototype for an object that defines a set of attributes that characterize any object of the class. The attributes are data members (class variables and instance variables) and methods, accessed via dot notation.

Class variable – A variable that is shared by all instances of a class. Class variables are defined within a class but outside any of the class's methods. Class variables are not used as frequently as instance variables are.

Data member – A class variable or instance variable that holds data associated with a class and its objects.

Function overloading – The assignment of more than one behavior to a particular function. The operation performed varies by the types of objects or arguments involved.

Instance variable – A variable that is defined inside a method and belongs only to the current instance of a class.

Inheritance – The transfer of the characteristics of a class to other classes that are derived from it.

Instance – An individual object of a certain class. An object obj that belongs to a class Circle, for example, is an instance of the class Circle.

Instantiation – The creation of an instance of a class.

Method – A special kind of function that is defined in a class definition.

Object – A unique instance of a data structure that's defined by its class. An object comprises both data members (class variables and instance variables) and methods.

Operator overloading – The assignment of more than one function to a particular operator.

Creating Classes

The class statement creates a new class definition. The name of the class immediately follows the keyword class followed by a colon as follows –

```
class ClassName:
    '''Optional class documentation string'''
    Class_suite
```

- The class has a documentation string, which can be accessed via `ClassName.__doc__`.
- The `class_suite` consists of all the component statements defining class members, data attributes and functions.

Following is an example of a simple Python class –

```
class Employee:
    '''Common base class for all employees'''
    empCount = 0

    def __init__(self, name, salary):
        self.name = name
        self.salary = salary
        Employee.empCount += 1

    def displayCount(self):
        print "Total Employee %d" % Employee.empCount

    def displayEmployee(self):
        print "Name : ", self.name, " , Salary: ", self.salary
```

- The variable `empCount` is a class variable whose value is shared among all instances of this class. This can be accessed as `Employee.empCount` from inside the class or outside the class.
- The first method `__init__()` is a special method, which is called class constructor or initialization method that Python calls when you create a new instance of this class.
- You declare other class methods like normal functions with the exception that the first argument to each method is `self`. Python adds the `self` argument to the list for you; you do not need to include it when you call the methods.

Creating Instance Objects

To create instances of a class, you call the class using class name and pass in whatever arguments its `__init__` method accepts.

```
"This would create first object of Employee class"
emp1 = Employee("Zara", 2000)
"This would create second object of Employee class"
emp2 = Employee("Manni", 5000)
```

Now, putting all the concepts together –

```
class Employee:
    'Common base class for all employees'
    empCount = 0

    def __init__(self, name, salary):
        self.name = name
        self.salary = salary
        Employee.empCount += 1

    def displayCount(self):
        print "Total Employee %d" % Employee.empCount

    def displayEmployee(self):
        print "Name : ", self.name, ", Salary: ", self.salary

"This would create first object of Employee class"
emp1 = Employee("Zara", 2000)
"This would create second object of Employee class"
emp2 = Employee("Manni", 5000)
emp1.displayEmployee()
emp2.displayEmployee()
print "Total Employee %d" % Employee.empCount
```

When the above code is executed, it produces the following result –

```
Name :  Zara ,Salary:  2000
Name :  Manni ,Salary:  5000
Total Employee 2
```

You can add, remove, or modify attributes of classes and objects at any time –

```
emp1.age = 7  # Add an 'age' attribute.
emp1.age = 8  # Modify 'age' attribute.
del emp1.age  # Delete 'age' attribute.
```

Instead of using the normal statements to access attributes, you can use the following functions –

- The `getattr(obj, name[, default])` – to access the attribute of object.
- The `hasattr(obj, name)` – to check if an attribute exists or not.
- The `setattr(obj, name, value)` – to set an attribute. If attribute does not exist, then it would be created.
- The `delattr(obj, name)` – to delete an attribute.

```

hasattr(emp1, 'age')      # Returns true if 'age' attribute
exists
getattr(emp1, 'age')     # Returns value of 'age' attribute
setattr(emp1, 'age', 8)  # Set attribute 'age' at 8
delattr(emp1, 'age')     # Delete attribute 'age'

```

Built-In Class Attributes

Every Python class keeps following built-in attributes and they can be accessed using dot operator like any other attribute –

```

__dict__: Dictionary containing the class's namespace.
__doc__: Class documentation string or none, if undefined.
__name__: Class name.
__module__: Module name in which the class is defined. This attribute is "__main__" in interactive mode.
__bases__: A possibly empty tuple containing the base classes, in the order of their occurrence in the base class list.

```

For the above class let us try to access all these attributes –

```

class Employee:
    'Common base class for all employees'
    empCount = 0

    def __init__(self, name, salary):
        self.name = name
        self.salary = salary
        Employee.empCount += 1

    def displayCount(self):
        print "Total Employee %d" % Employee.empCount

    def displayEmployee(self):
        print "Name : ", self.name, " , Salary: ", self.salary

print "Employee.__doc__:", Employee.__doc__
print "Employee.__name__:", Employee.__name__
print "Employee.__module__:", Employee.__module__
print "Employee.__bases__:", Employee.__bases__
print "Employee.__dict__:", Employee.__dict__

```

When the above code is executed, it produces the following result –

```

Employee.__doc__: Common base class for all employees
Employee.__name__: Employee

```

```

Employee.__module__: __main__
Employee.__bases__: ()
Employee.__dict__: {'__module__': '__main__', 'displayCount':
<function displayCount at 0xb7c84994>, 'empCount': 2,
'displayEmployee': <function displayEmployee at 0xb7c8441c>,
'__doc__': 'Common base class for all employees',
'__init__': <function __init__ at 0xb7c846bc>}

```

Destroying Objects (Garbage Collection)

Python deletes unneeded objects (built-in types or class instances) automatically to free the memory space. The process by which Python periodically reclaims blocks of memory that no longer are in use is termed Garbage Collection. Python's garbage collector runs during program execution and is triggered when an object's reference count reaches zero. An object's reference count changes as the number of aliases that point to it changes. An object's reference count increases when it is assigned a new name or placed in a container (list, tuple, or dictionary). The object's reference count decreases when it's deleted with `del`, its reference is reassigned, or its reference goes out of scope. When an object's reference count reaches zero, Python collects it automatically.

```

a = 40          # Create object <40>
b = a          # Increase ref. count  of <40>
c = [b]        # Increase ref. count  of <40>

del a          # Decrease ref. count  of <40>
b = 100        # Decrease ref. count  of <40>
c[0] = -1      # Decrease ref. count  of <40>

```

You normally will not notice when the garbage collector destroys an orphaned instance and reclaims its space. But a class can implement the special method `__del__()`, called a destructor, that is invoked when the instance is about to be destroyed. This method might be used to clean up any non memory resources used by an instance.

This `__del__()` destructor prints the class name of an instance that is about to be destroyed –

```

class Point:
    def __init__( self, x=0, y=0):
        self.x = x
        self.y = y
    def __del__(self):
        class_name = self.__class__.__name__
        print class_name, "destroyed"

pt1 = Point()
pt2 = pt1
pt3 = pt1

```

```
print id(pt1), id(pt2), id(pt3) # prints the ids of the objects
del pt1
del pt2
del pt3
```

When the above code is executed, it produces following result –

```
3083401324 3083401324 3083401324
Point destroyed
```

Ideally, you should define your classes in separate file, then you should import them in your main program file using import statement.

Class Inheritance

Instead of starting from scratch, you can create a class by deriving it from a preexisting class by listing the parent class in parentheses after the new class name. The child class inherits the attributes of its parent class, and you can use those attributes as if they were defined in the child class. A child class can also override data members and methods from the parent.

Syntax

Derived classes are declared much like their parent class; however, a list of base classes to inherit from is given after the class name –

```
class SubClassName (ParentClass1[, ParentClass2, ...]):
    'Optional class documentation string'
    Class_suite
```

For example consider the following example:

```
class Parent:          # define parent class
    parentAttr = 100
    def __init__(self):
        print "Calling parent constructor"

    def parentMethod(self):
        print 'Calling parent method'

    def setAttr(self, attr):
        Parent.parentAttr = attr

    def getAttr(self):
        print "Parent attribute :", Parent.parentAttr

class Child(Parent): # define child class
```

```

def __init__(self):
    print "Calling child constructor"

def childMethod(self):
    print 'Calling child method'

c = Child()          # instance of child
c.childMethod()      # child calls its method
c.parentMethod()     # calls parent's method
c.setAttr(200)       # again call parent's method
c.getAttr()          # again call parent's method

```

When the above code is executed, it produces the following result –

```

Calling child constructor
Calling child method
Calling parent method
Parent attribute : 200

```

Similar way, you can drive a class from multiple parent classes as follows –

```

class A:              # define your class A
.....

class B:              # define your class B
.....

class C(A, B):        # subclass of A and B
.....

```

You can use `issubclass()` or `isinstance()` functions to check a relationships of two classes and instances.

- The `issubclass(sub, sup)` boolean function returns true if the given subclass `sub` is indeed a subclass of the superclass `sup`.
- The `isinstance(obj, Class)` boolean function returns true if `obj` is an instance of class `Class` or is an instance of a subclass of `Class`

Overriding Methods

You can always override your parent class methods. One reason for overriding parent's methods is because you may want special or different functionality in your subclass.

```

class Parent:         # define parent class
    def myMethod(self):
        print 'Calling parent method'

```

```

class Child(Parent): # define child class
    def myMethod(self):
        print 'Calling child method'

c = Child()           # instance of child
c.myMethod()          # child calls overridden method

```

When the above code is executed, it produces the following result –

```

Calling child method

```

Overloading Operators

Suppose you have created a Vector class to represent two-dimensional vectors, what happens when you use the plus operator to add them? Most likely Python will yell at you. You could, however, define the `__add__` method in your class to perform vector addition and then the plus operator would behave as per expectation –

```

class Vector:
    def __init__(self, a, b):
        self.a = a
        self.b = b

    def __str__(self):
        return 'Vector (%d, %d)' % (self.a, self.b)

    def __add__(self, other):
        return Vector(self.a + other.a, self.b + other.b)

v1 = Vector(2,10)
v2 = Vector(5,-2)
print v1 + v2

```

When the above code is executed, it produces the following result –

```

Vector(7,8)

```

Data Hiding

An object's attributes may or may not be visible outside the class definition. You need to name attributes with a double underscore prefix, and those attributes then are not directly visible to outsiders.

```

class JustCounter:
    __secretCount = 0

    def count(self):

```

```

        self.__secretCount += 1
        print self.__secretCount

counter = JustCounter()
counter.count()
counter.count()
print counter.__secretCount

```

When the above code is executed, it produces the following result –

```

1
2
Traceback (most recent call last):
  File "test.py", line 12, in <module>
    print counter.__secretCount
AttributeError: JustCounter instance has no attribute
'__secretCount'

```

Python protects those members by internally changing the name to include the class name. You can access such attributes as `object._className__attrName`. If you would replace your last line as following, then it works for you –

```

.....
print counter._JustCounter__secretCount

```

When the above code is executed, it produces the following result –

```

1
2
2

```

Exercises

1. Write a Python class to convert an integer to a roman numeral.
2. Write a Python class to find validity of a string of parentheses, '(', ')', '{', '}', '[' and ']'. These brackets must be close in the correct order, for example "()" and "()[{}]" are valid but "[)", "({[})]" and "{{{" are invalid.
3. Write a Python class to get all possible unique subsets from a set of distinct integers.
Input : [4, 5, 6]
Output : [], [6], [5], [5, 6], [4], [4, 6], [4, 5], [4, 5, 6]
4. Write a Python class to find the three elements that sum to zero from a set of n real numbers.
Input array : [-25, -10, -7, -3, 2, 4, 8, 10]
Output : [[-10, 2, 8], [-7, -3, 10]]
5. Write a Python class to implement pow(x, n).
6. Write a Python class to reverse a string word by word. - Go to the editor
Input string : 'hello .py'
Expected Output : '.py hello'
7. Write a Python class which has two methods get_String and print_String. get_String accept a string from the user and print_String print the string in upper case.
8. Write a Python class named Rectangle constructed by a length and width and a method which will compute the area of a rectangle.
9. Write a Python class named Circle constructed by a radius and two methods which will compute the area and the perimeter of a circle.
